

## Lecture-11

### Functions

#### 11.1 Arguments passed by value and by reference.

Until now, in all the functions we have seen, the arguments passed to the functions have been passed *by value*. This means that when calling a function with parameters, what we have passed to the function were copies of their values but never the variables themselves. For example, suppose that we called our first function addition using the following code:

```
int x=5, y=3, z;  
z = addition ( x , y );
```

What we did in this case was to call to function addition passing the values of x and y, i.e. 5 and 3 respectively, but not the variables x and y themselves.

```
int addition (int a, int b)  
z = addition ( 5 , 3 );
```

This way, when the function addition is called, the value of its local variables a and b become 5 and 3 respectively, but any modification to either a or b within the function addition will not have any effect in the values of x and y outside it, because variables x and y were not themselves passed to the function, but only copies of their values at the moment the function was called.

*But there might be some cases where you need to manipulate from inside a function the value of an external variable.* For that purpose we can use **arguments passed by reference**, as in the function duplicate of the following example:

#### Program 11.1 Passing parameters by reference

```
// passing parameters by reference  
#include <iostream>  
using namespace std;  
  
void duplicate (int& a, int& b, int& c)  
{  
    a*=2;           //x,y,z have been multiplied by 2  
    b*=2;  
    c*=2;  
}  
  
int main ()  
{
```

```

int x=1, y=3, z=7;
duplicate (x, y, z);
cout << "x=" << x << ", y=" << y << ", z=" << z;
return 0;
}
OUTPUT
/* x=2, y=6, z=14 */

```

The first thing that should call your attention is that in the declaration of duplicate the type of each parameter was followed by an ampersand sign (&). This ampersand is what specifies that their corresponding arguments are to be passed *by reference* instead of *by value*.

When a variable is passed by reference we are not passing a copy of its value, but we are somehow passing the variable itself to the function and any modification that we do to the local variables will have an effect in their counterpart variables passed as arguments in the call to the function.

```

void duplicate (int& a, int& b, int& c)
                ↑x      ↑y      ↑z
duplicate (  x  ,  y  ,  z  );

```

To explain it in another way, we associate a, b and c with the arguments passed on the function call (x, y and z) and any change that we do on a within the function will affect the value of x outside it. Any change that we do on b will affect y, and the same with c and z.

That is why our program's output, that shows the values stored in x, y and z after the call to duplicate, shows the values of all the three variables of main doubled.

If when declaring the following function:

```
void duplicate (int& a, int& b, int& c)
```

we had declared it this way:

```
void duplicate (int a, int b, int c)
```

i.e., without the ampersand signs (&), we would have not passed the variables by reference, but a *copy of their values* instead, and therefore, the output on screen of our program would have been the values of x, y and z without having been modified.

Passing by reference is also an effective way to allow a function to **return more than one value**. For example, here is a function that returns the previous and next numbers of the first parameter passed.

## Programm11.2: Returning multiple values

```
// more than one returning value
#include <iostream>
using namespace std;

void prevnext (int x, int& prev, int& next)
{
    prev = x-1;
    next = x+1;
}

int main ()
{
    int x=100, y, z;
    prevnext (x, y, z);
    cout << "Previous=" << y << ", Next=" << z;
    return 0;
}
OUTPUT
/* Previous=99, Next=101 */
```

## 11.2 Default values in parameters.

When declaring a function we can specify a default value for each parameter. This value will be used if the corresponding argument is left blank when calling to the function. To do that, we simply have to use the assignment operator and a value for the arguments in the function declaration. *If a value for that parameter is not passed when the function is called, the default value is used*, but if a value is specified this default value is ignored and the passed value is used instead. For example:

### Program, 11.3 :Default Values in Function

```
// default values in functions
#include <iostream>
using namespace std;

int divide (int a, int b=2) // here b is the default value
{
    float r;
    r=a/b;
    return (r);
}

int main ()
{
    cout << divide (12);
    cout << endl;
    cout << divide (20,4);
    return 0;
}
```

OUTPUT

```
/*6  
5  
*/
```

As we can see in the body of the program there are two calls to function divide. In the first one:

**divide (12)**

we have only specified one argument, but the function divide allows up to two. So the function divide has assumed that the second parameter is 2 since that is what we have specified to happen if this parameter was not passed (notice the function declaration, which finishes with `int b=2`, not just `int b`). Therefore the result of this function call is 6 (12/2).

In the second call:

**divide (20,4)**

there are two parameters, so the default value for `b` (`int b=2`) is ignored and `b` takes the value passed as argument, that is 4, making the result returned equal to 5 (20/4).

### 11.3 Overloaded functions.

In C++ two different functions can have the same name if their parameter types or number are different. That means that you can give the same name to more than one function if they have either a different number of parameters or different types in their parameters. For example:

#### Program 11.4 :Overloaded function.

```
// overloaded function  
#include <iostream>  
using namespace std;  
  
int operate (int a, int b)  
{  
    return (a*b);  
}  
  
float operate (float a, float b)  
{  
    return (a/b);  
}  
  
int main ( )  
{  
    int x=5,y=2;
```

```

float n=5.0,m=2.0;
cout << operate (x,y);
cout << "\n";
cout << operate (n,m);
cout << "\n";
return 0;
}
/* 10
2.5
*/

```

In this case we have defined two functions with the same name, `operate`, but one of them accepts two parameters of type `int` and the other one accepts them of type `float`. The compiler knows which one to call in each case by examining the types passed as arguments when the function is called. If it is called with two `ints` as its arguments it calls to the function that has two `int` parameters in its prototype and if it is called with two `floats` it will call to the one which has two `float` parameters in its *prototype*.

In the first call to `operate` the two arguments passed are of type `int`, therefore, the function with the first prototype is called; This function returns the result of multiplying both parameters. While the second call passes two arguments of type `float`, so the function with the second prototype is called. This one has a different behavior: it divides one parameter by the other. So the behavior of a call to `operate` depends on the type of the arguments passed because the function has been *overloaded*.

**NB:** Notice that a function cannot be overloaded only by its return type. At least one of its parameters must have a different type.

#### 11.4 inline functions.

The inline function looks like normal functions but they insert the function code directly into the calling program. Inline functions execute faster than the normal functions. It does not change the behavior of a function, but serves to indicate the compiler that the code the function body generates shall be inserted at the point of each call to the function. This is equivalent to declaring a macro. It only represents an overhead advantage for very short functions, in which the resulting code from compiling the program may be faster when the overhead required to call a function is avoided.

The format for its declaration is:

```
inline type name ( arguments ... ) { instructions ... }
```

and the call is just like the call to any other function. One does not have to include the `inline` keyword when calling the function, only in its declaration.

Most compilers already optimize code to generate inline functions when it is more convenient. This specifier only indicates the compiler that inline is preferred for this function.

### Program 11.5

```
#include <iostream>
#include <math.h>
inline double hypotenuse(double a,double b)
{
Return sqrt(a*a+b*b);
}
void main ( )
{
double k=6, m=9;
//Next to line execute the same results
cout<<hypotenuse(k,m)<<endl;
cout<<sqrt(k*k+m*m)<<endl;
}
```

### 11.5 Recursivity.

Recursivity is the property that functions have to be called by themselves. It is useful for many tasks, like sorting or calculate the factorial of numbers. For example, to obtain the factorial of a number (n!) the mathematical formula would be:

$$n! = n * (n-1) * (n-2) * (n-3) \dots * 1$$

more concretely, 5! (factorial of 5) would be:

$$5! = 5 * 4 * 3 * 2 * 1 = 120$$

and a recursive function to calculate this in C++ could be:

### Program 11.6: Factorial of a number

```
// factorial calculator
#include <iostream>
using namespace std;

long factorial (long a)
{
if (a > 1)
return (a * factorial (a-1));
else
return (1);
}
```

```

int main ()
{
    long number;
    cout << "Please type a number: ";
    cin >> number;
    cout << number << "! = " << factorial (number);
    return 0;
}

```

## OUTPUT

```
/* Please type a number: 9
```

```
9! = 362880 */
```

Notice how in function factorial we included a call to itself, but only if the argument passed was greater than 1, since otherwise the function would perform an infinite recursive loop in which once it arrived to 0 it would continue multiplying by all the negative numbers (probably provoking a stack overflow error on runtime).

This function has a limitation because of the data type we used in its design (long) for more simplicity. The results given will not be valid for values much greater than 10! or 15!, depending on the system you compile it.

## 11.6 DECLARING FUNCTIONS.

Until now, we have defined all of the functions before the first appearance of calls to them in the source code. These calls were generally in function main which we have always left at the end of the source code. But if you try to repeat some of the examples of functions described so far, but placing the function main before any of the other functions that were called from within it, you will most likely obtain compiling errors. The reason is that to be able to call a function this must have been declared in some earlier point of the code, like we have done in all our examples.

But there is an alternative way to avoid writing the whole code of a function before it can be used in main or in some other function. This can be achieved by declaring just a prototype of the function before it is used, instead of the entire definition. This declaration is shorter than the entire definition, but significant enough for the compiler to determine its return type and the types of its parameters.

Its form is:

```
type name ( argument_type1, argument_type2, ...);
```

It is identical to a function definition, except that it does not include the body of the function itself (i.e., the function statements that in normal definitions are enclosed in braces { }) and instead of that we end the prototype declaration with a mandatory semicolon (;).

The parameter enumeration does not need to include the *identifiers*, but only the type *specifiers*. The inclusion of a name for each parameter as in the function definition is optional in the prototype declaration. For example, we can declare a function called `protofunction` with two `int` parameters with any of the following declarations:

```
int protofunction (int first, int second);  
int protofunction (int, int);
```

Anyway, including a name for each variable makes the prototype more legible.

```
// declaring functions prototypes
```

```
#include <iostream>  
using namespace std;
```

```
void odd (int a);  
void even (int a);
```

```
int main ()  
{  
    int i;  
    do {  
        cout << "Type a number: (0 to exit) ";  
        cin >> i;  
        odd (i);  
    } while (i!=0);  
    return 0;  
}
```

```
void odd (int a)  
{  
    if ((a%2)!=0) cout << "Number is odd.\n";  
    else even (a);  
}
```

```
void even (int a)  
{  
    if ((a%2)==0) cout << "Number is even.\n";  
    else odd (a);  
}
```

```
OUTPUT
```

```
/*
```

```
Type a number (0 to exit): 9
```

```
Number is odd.
```

```
Type a number (0 to exit): 6
```

```
Number is even.
```

```
Type a number (0 to exit): 1030
```

```
Number is even.  
*/
```

This example illustrates how prototyping works. Moreover, in this concrete example the prototyping of at least one of the two functions is necessary in order to compile the code without errors.

The first things that we see are the declaration of functions odd and even:

```
void odd (int a);  
void even (int a);
```

This allows these functions to be used before they are defined, for example, in main, which now is located where some people find it to be a more logical place for the start of a program: the beginning of the source code.

Anyway, the reason why this program needs at least one of the functions to be declared before it is defined is because in odd there is a call to even and in even there is a call to odd. If none of the two functions had been previously declared, a compilation error would happen, since either odd would not be visible from even (because it has still not been declared), or even would not be visible from odd (for the same reason).

Having the prototype of all functions together in the same place within the source code is found practical by some programmers, and this can be easily achieved by declaring all functions prototypes at the beginning of a program.

### **PROGRAM: 11.7 : Summation of a series sum=1!+2!+3!+....**

```
//Program for sum=1!+2!+3!+....  
  
#include <iostream>  
#include <conio.h> /*_getchar() is included in this header.  
                This is a c header file, that is why  
                .h is put in the end.*/  
  
using namespace std;  
int fact(int);  
void main()  
{  
    int s,n;  
    int num(int);  
    //clrscr();  
    cout<<"\nEnter a number:";  
    cin>>n;  
    s=num(n);  
    cout<<"\nTotal sum of factorials="<<s;  
    _getch();//getch() gives arning  
}  
//function num()  
int num(int n)  
{
```

```

    //long int f;
    long int s=0;
    for(int i=1; i<=n; i++)
    {
        //f=fact(n);
        s=s+fact(i);
        cout<<"Factorial of\t "<<i<<"is\t"<<fact(i)<<"and sum
is\t"<<s<<"\n";
    }
    return s;
}
//Factorial function
int fact (int x)
{
    long int f=1,j;
    for(j=1; j<=x; j++)
        f=f*j;
    return f;
}
/*

```

Enter a number:10

```

Factorial of    1is    1and sum is    1
Factorial of    2is    2and sum is    3
Factorial of    3is    6and sum is    9
Factorial of    4is    24and sum is    33
Factorial of    5is    120and sum is    153
Factorial of    6is    720and sum is    873
Factorial of    7is    5040and sum is    5913
Factorial of    8is    40320and sum is    46233
Factorial of    9is    362880and sum is    409113
Factorial of   10is    3628800and sum is    4037913

```

Total sum of factorials=4037913

\*/
